

Exploring ironmaking practice at Meroe, Sudan—images, data, and analytical scripts

Michael F. Charlton¹

Jane Humphris¹

¹*UCL Qatar*

27 July 2017

Introduction

Meroe, Sudan was an important ironmaking centre for the Kingdom of Kush between the 7th Century BC and the 4th Century AD (Humphris and Rehren, 2014). Following excavation of a furnace workshop beneath the 2nd - 4th Century AD slag heap labeled MIS6, a series of iron production experiments were conducted in January 2015 in order to test technological models and investigate resource utilization. Analysis of smelting residues from the MIS6 workshop and the experiments subsequently took place at UCL Qatar in late 2016.

Methods

Residues were submitted to the UCL Qatar Archaeological Materials Laboratories in Doha, where they were catalogued, sectioned, cleaned, and mounted in epoxy resin blocks. Each specimen was polished following standard metallographic techniques to a finish of 1 μm . Specimens were investigated via optical microscopy and given a secondary material identification. These were then coated with carbon and re-examined with scanning electron microscopy (SEM) and energy dispersive (EDS) X-ray microanalysis.

Optical microscopy

Polished specimens were investigated with reflected light microscopy using a Leica DM 2500P at variable magnifications. Notes were taken and a series of images generated for later reference. Most of the images are not created at typical publication standards, but are provided in this dataset for their information content. Files consist of up to 6 stacked images in a TIFF format to enable quick examination of specimen variability. **ImageJ** (Schindelin et al., 2015) is the recommended software package for exploring the stacks.

Scanning Electron Microscopy and X-ray microanalysis

Carbon-coated specimens were explored with a JEOL JSM 6610 low vacuum SEM equipped with an Oxford Instruments X-Max N50 energy dispersive spectrometer (EDS). Images were captured with backscattered electrons to observe phase differences, and element compositional analyses conducted for each. X-ray spectra were acquired, interrogated, and quantified using Oxford Instruments Aztec 3.1. Spectra were optimized using a cobalt standard and acquisition parameters were kept constant (working distance = 10 mm; accelerating voltage = 20kV; process time = 5; deadtime \approx 40%). All EDS analyses were conducted at magnifications of x200 or greater, most comprising area scans at x200. Peak identifications were made manually in order to optimize each fitted spectrum to its empirical spectrum and identify anomalies created by the pulse pile up correction algorithm. Images for all area analyses are provided in this dataset and can be compared with the raw analytical data for each in the *.RData*, *.txt*, and *.xlsx* files named **Meroe XP and MIS6 SEM-EDS data**. Files consist of 5 analytical images stacked into a TIFF format to enable quick examination of specimen variability. **ImageJ** (Schindelin et al., 2015) is the recommended software package for exploring the stacks.

Data quality

Three certified reference materials (CRMs) were analysed during most analytical sessions to ensure good instrument performance and provide a means of assessing the precision and accuracy of quantified results. The US Geological Survey CRM basalts BCR-2G (Plumlee, 1998a), BIR-1G (Smith, 1998), and BHVO-2G (Plumlee, 1998b), were selected. Results deviated from the recommended values and between runs due to variations in beam current and minor differences in focusing. Normalization across all identified elements, however, leads to general increases in accuracies and precision for most elements with recommended values greater than 0.1 wt %. Interested readers are invited to explore the data acquired for each CRM during this study as provided in the *.RData*, *.txt*, and *.xlsx* files named **CRM Analyses**.

Data analysis

A key component of the Sudan Project's activities at Meroe is to identify the resources exploited by ancient smelters. This task can be complicated by the fact that iron production generates a range of material products with blurred definitions. Following macro- and microscopic materials characterization, data must be sorted into chemical groups that enable comparisons between functionally similar materials.

The script and output below provide a detailed account of how the experimental and archaeological ironmaking residues were sorted into chemical groups for the aims of this project. The approach taken relies on the iterative use of principal component analysis (PCA) and hierarchical cluster analysis (HCA). A final set of comparisons are made with data converted into oxides via stoichiometry.

Code for the specialized plotting and analysis functions can be found in the attached script and PDF documents named ***Custom plotting and related functions for compositional data analysis***. All analyses were written in RStudio 1.0.146 and performed using R version 3.4.1 (R Core Team, 2017). In addition to the base package, scripts require functions found in the MASS (Venables and Ripley, 2002) and robCompositions (Templ et al., 2011) libraries. Users are invited to explore our results using the code below by applying it to the associated dataset. They are also encouraged to modify related functions and scripts to explore this and other datasets with similar data. However, caution is warranted when comparing these analyses to those produced by of other laboratories and projects without due consideration to data quality biases.

Load relevant packages:

Load data

```
data<-read.csv(file=file.choose(),header=TRUE, row.names=1)
```

Normalize data

Short term drift in the electron beam current of scanning electron microscopes introduces variation in quantitative measures of element composition. The normalization process assumes that such measurement noise is uniform across all beam measures with totals approaching 100 wt%. Analysis of fused basalt CRMs shows this to be the case. Additional error is introduced by

imperfect sample preparation, the presence of voids, and sample matrix. The degree to which normalization also corrects for these is unknown, though similarly prepared samples with equivalent matrices are expected to exhibit comparable levels of uncertainty.

```
data.meas<-data[data$measure=="measure" | data$measure=="single",]  
sum.data<-apply(data.meas[els.all],1,sum)  
norm.data<-data.meas[els.all]/sum.data*100  
data.meas[els.all]<-norm.data
```

Calculate sample means

In general, chemical composition was measured in five areas for each specimen. Mean chemistries are assumed to be characteristic of the specimen as a whole and are calculated prior to making further comparisons.

```
spec<-NULL  
spec.mean<-NULL  
for(i in 1:nlevels(data.meas$lab.spec)){  
  spec[[i]]<-data.meas[data.meas$lab.spec==levels(data.meas$lab.spec)[i],]  
  for(j in 1:length(spec)){  
    spec.mean[[j]]<-colMeans(spec[[j]][els.all])  
  }  
}  
  
data.mean<-data.meas[FALSE,]  
for(m in 1:length(spec.mean)){  
  data.mean[m,els.all]<-t(as.data.frame(spec.mean[[m]]))  
  data.mean[m,data.meta]<-as.data.frame(spec[[m]][nrow(spec[[m])],data.meta])  
  data.mean$measure[m]<-"mean"  
  data.mean$image[m]<-"mean"  
}  
  
rownames(data.mean)<-data.mean$lab.spec
```

Calculate sample standard deviations for each specimen

The calculation of specimen standard deviations facilitates the assessment of variable uncertainty.

```
data.sdev<-data.mean[FALSE,]  
for(k in 1:length(spec)){  
  for(l in 1:length(els.all)){  
    data.sdev[k,els.all][,l]<-sd(spec[[k]][els.all][,l])  
  }  
}
```

```

data.sdev[k,data.meta]<-data.mean[k,data.meta]
data.sdev$measure[k]<-"sdev"
data.sdev$image[k]<-"sdev"
}
}

rownames(data.sdev)<-paste(rownames(data.mean),"_sdev",sep="")

```

Impute rounded zeros

Missing variables arising from each area scan were assumed to be below detection. These were given a nominal value of zero. Where the variable mean is exactly equal to zero across all, that variable is not considered for further analysis. Otherwise, all zeros are imputed using the **impRZilr()** function from the **robCompositions** package (Templ et al., 2011). The elements O and Cl are then removed from interest because it is assumed that they add noise to the residues of metallurgical systems. The rest become part of the working data in the dataframe **data.wk**.

```

els.imp<-c()
n<-0
for(t in 1:length(els.all)){
  if(colMeans(data.mean[els.all])[t]==0){
    next
  }else{
    n<-n+1
    els.imp[n]<-els.all[t]
  }
}

data.imp<-impRZilr(data.mean[els.imp],dl=rep(0.001,ncol(data.mean[els.imp])))
data.mean[els.imp]<-data.imp$x

els<-els.imp[which(els.imp!=c("O","Cl"))]

data.wk<-data.mean

```

Multivariate analysis of ore chemistry

Identification of furnace workshop ores

Potential ore residues were sampled from MIS6-FW224, the furnace fill. All of these were assumed to be partially reacted. In order to determine which were closer to the actual ore used, a systematic examination and sorting of materials from the furnace fill was undertaken.

Multivariate analysis of slag

Identification of furnace workshop slag

Iron production residues were sampled from two contexts within the MIS6 furnace workshop: a) MIS6-FW224--furnace fill and b) MIS6-FW262--probable smithing hearth. These two types of slag, as well as other potential outliers, needed to be identified and separated prior to comparisons of smelting slag.

write.csv(tc.wk,file=file.choose())
```

Analysis of oxide data

Most traditional analysis of slag chemistry makes use of oxide rather than elemental wt % data. This approach assumes that most elements are bound with oxygen into common oxide molecules; an assumption validated by examination of specimen phase structure. These common oxides are calculated via stoichiometry using multipliers that define changes in mass between an element and its specified molecule.

The scripts below use stoichiometry to convert elements to oxides. The multipliers used in this study can be found in the *.RData* file named **SEM_element-oxide conversion factors**. Select oxides are then plotted into the FeO-SiO₂-Al₂O₃ ternary phase diagram. This diagram serves as a model for slag thermochemical behavior. Finally, the Reducible Iron Index (RII; Charlton et al., 2010) is calculated as an estimate of furnace redox conditions. The appropriate use of the RII depends on an accurate knowledge and consideration of ceramic and fuel-ash influences on slag chemistry. These were not available for this study, and the plots are provided solely for information and comparison.

convert elements to oxide wt %

```
ocf<-read.csv(file=file.choose(),header=T,row.names=1)
els.ocf<-colnames(ocf)
els.ocf<-els.ocf[which(els.ocf!="Hf" & els.ocf!="As")]
data.change<-data.wk[els.ox]

for(c in 1:ncol(data.change)){
  data.change[,c]<-as.numeric(data.change[,c])
}

data.wk[colnames(data.change)]<-data.change

ocf2<-t(ocf[els.ox])

ox.dat<-array(data=NA, dim=c(nrow(data.wk),ncol(data.wk[els.ox])))
for(r in 1:nrow(data.wk)){
  for(c in 1:ncol(data.wk[els.ox])){
    ox.dat[r,c]<-data.wk[els.ox][r,c]*ocf[els.ox][,c]
  }
}

values<-c(rep(NA,length(data.meta)), rep("wt %",length(ox.per)))
rownames(ox.dat)<-rownames(data.wk)
```

```
colnames(ox.dat)<-ox.per
ox.dat<-data.frame(ox.dat)
ox.dat.per<-round(ox.dat[ox.per],3)
ox.dat<-cbind(data.wk[data.meta], ox.dat.per)
colnames(ox.dat)<-c(data.meta,ox.per)
```

calculate RII

```
rII<-2.39*ox.dat$SiO2/(ox.dat$MnO+ox.dat$FeO)
ox.dat<-cbind(ox.dat,rII)
```

create CSV file for oxide dataset

```
write.csv(ox.dat,file=file.choose())
```

subset slag oxide data

```
slag.ox<-ox.dat[rownames(slag.wk5),]
slag.ox<-droplevels(slag.ox)
```

Plot slag data in FeO-SiO₂-Al₂O₃ ternary phase diagram

select and transform ternary data

```
tern.data<-slag.ox

tern.sum<-apply(tern.data[tern.els],1,sum)

tern.data["FeO.MnO"]<-tern.data["FeO"]+tern.data["MnO"]

tern.data["FeO.MnO"]<-(tern.data["FeO.MnO"])/tern.sum*100
tern.data["SiO2"]<-tern.data["SiO2"]/tern.sum*100
tern.data["Al2O3"]<-tern.data["Al2O3"]/tern.sum*100
```

define liquidus lines

Ternary liquidus lines display the shifting equilibrium freezing temperatures across phases compositions displayed in the ternary phase diagram. Here, those lines are smoothed across a series of points measured from the FeO-SiO₂-Al₂O₃ ternary system given in Levin et al. (1964). The points are given in the *.RData* file named **FeO-SiO2-Al2O3 lines**.

```

Acknowledgements

Permission for the research to be carried out at Meroe is granted by the National Corporation for Antiquities and Museums in Sudan, and for their assistance and continual support we are sincerely thankful. A number of organisations provide collaborations and funding through with various aspects of this research have been greatly assisted. These include the Qatar-Sudan Archaeology Project, UCL Qatar, the University of Khartoum, and the British Institute in Eastern Africa. Michael Charlton's participation and research was supported by a Marie Curie International Incoming Fellowship (PIIF-GA-2013-624448) within the 7th European Community Framework Programme as part of the IRONWORKS project. All samples were prepared by Loic Boscher. Additional support with sample selection and preparation was provided by Philip Connelly, Tom Birch, and Fareed Alshishani. Special thanks go to smelters Jake Keen and Lee Sauder for conducting the experiments and Suleiman Awad Suleiman, Thomas Scheibner and Saskia Büchner for constant and multifaceted support throughout the project.
